

A Cookbook for Using the Model-View-Controller User Interface Paradigm in Smalltalk-80

Glenn E. Krasner
Stephen T. Pope

Introduction

The user interface of the Smalltalk-80™ programming environment (see references, [Goldberg 83]) was developed using a particular strategy of representing information, display, and control. This strategy was chosen to satisfy two goals: (1) to create the special set of system components needed to support a highly interactive software development process; and (2) to provide a general set of system components that make it possible for programmers to create portable interactive graphical applications easily.

In this article we assume that the reader has a basic knowledge of the Smalltalk-80 language and programming environment. Interested readers not familiar with these are referred to [Goldberg and Robson 83] and [Goldberg 83] for introductory and tutorial material.

MVC and the Issues of Reusability and Pluggability

When building interactive applications, as with other programs, modularity of components has enormous benefits. Isolating functional units from each other as much as possible makes it easier for the application designer to understand and modify each particular unit, without having to know everything about the other units. Our experiences with the Smalltalk-76 programming system showed that one particular form of modularity—a three-way separation of application components—has payoff beyond merely making the designer's life easier. This three-way division of an application entails separating (1) the parts that represent the model of the underlying application domain from, (2) the way the model is presented to the user and from, and (3) the way the user interacts with it.

Model-View-Controller (MVC) programming is the application of this three-way factoring, whereby objects of different classes take over the operations related to the application domain (the model), the display of the application's state (the view), and the user interaction with the model and the view (the controller). In earlier Smalltalk system user interfaces, the tools that were put into the interface tended to consist of arrangements of four basic viewing idioms: paragraphs of text, lists of text (menus), choice "buttons," and graphical forms (bit- or pixel-maps). These tools also tended to use three basic user interaction paradigms: browsing, inspecting, and editing. A goal of the current Smalltalk-80 system was to be able to define user interface components for handling these idioms and paradigms once, and share them among all the programming environment tools and user-written applications using the methodology of MVC programming.

We also envisioned that the MVC methodology would allow programmers to write an application model by first defining new classes that would embody the special application domain-specific information. They would then design a user interface to it by laying out a composite view (window) for it by "plugging in" instances taken from the pre-defined user interface classes. This "pluggability" was desirable not only for viewing idioms, but also for implementing the controlling (editing) paradigms. Although certainly related in an interactive application, there is an advantage to being able to separate the functionality between how the model is displayed, and the methods for interacting with it. The use of pop-up versus fixed menus, the meaning attached to keyboard and mouse/function key, and scheduling of multiple views should be choices that can be made independently of the model or its view(s). They are choices that may be left up to the end user where appropriate.

The Model-View-Controller Metaphor

To address the issues outlined above, the Model-View-Controller metaphor and its application structuring paradigm for thinking about (and implementing) interactive application com-

Author's Address: ParcPlace Systems, 2400 Geng Road Palo Alto, CA 94303.
glenn@ParcPlace.com.

ponents was developed. *Models* are those components of the system application that actually do the work (simulation of the application domain). They are kept quite distinct from *views*, which display aspects of the models. *Controllers* are used to send messages to the model, and provide the interface between the model with its associated views and the interactive user interface devices (e.g., keyboard, mouse). Each view may be thought of as being closely associated with a controller, each having exactly one model, but a model may have many view/controller pairs.

Models

The model of an application is the domain-specific software simulation or implementation of the application's central structure. This can be as simple as an integer (as the model of a counter) or string (as the model of a text editor), or it can be a complex object that is an instance of a subclass of some Smalltalk-80 collection or other composite class. Several examples of models will be discussed in the following sections of this article.

Views

In this metaphor, views deal with everything graphical: they request data from their model, and display the data. They contain not only the components needed for displaying but can also contain subviews and be contained within superviews. The superview provides ability to perform graphical transformations, windowing, and clipping between the levels of this subview/superview hierarchy. Display messages are often passed from the top-level view (the standard system view of the application window) through to the subviews (the view objects used in the subviews of the top-level view).

CONTROLLERS

Controllers contain the interface between their associated models and views and the input devices (e.g., keyboard, pointing device, time). Controllers also deal with scheduling interactions with other view-controller pairs: they track mouse movement between application views, and implement messages for mouse button activity and input from the input sensor. Although menus can be thought of as view-controller pairs, they are more typically considered input devices, and therefore are in the realm of controllers.

Broadcasting Change

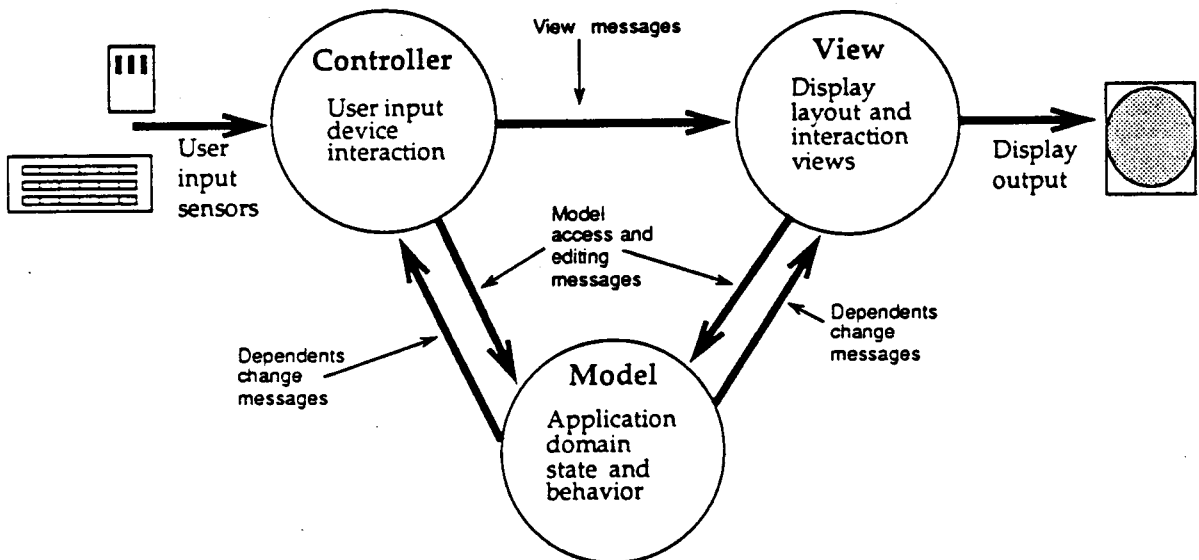

In the scheme described above, views and controllers have exactly one model, but a model can have one or several views and controllers associated with it. To maximize data encapsulation and thus code reusability, views and controllers need to know about their model explicitly, but models should not know about their views and controllers.

A change in a model is often triggered by a controller connecting a user action to a message sent to the model. This change should be reflected in all of its views, not just the view associated with the controller that initiated the change.

Dependents

To manage change notification, the notion of objects as *dependents* was developed. Views and controllers of a model are registered in a list as dependents of the model, to be informed whenever some aspect of the model is changed. When a model has changed, a message is broadcast to notify all of its dependents about the change. This message can be parameterized (with arguments), so that there can be many types of model

Figure 1. Model-View-Controller State and Message Sending

change messages. Each view or controller responds to the appropriate model changes in the appropriate manner.

A Standard for the Interaction Cycle

The standard interaction cycle in the Model-View-Controller metaphor, then, is that the user takes some input action and the active controller notifies the model to change itself accordingly. The model carries out the prescribed operations, possibly changing its state, and broadcasts to its dependents (views and controllers) that it has changed, possibly telling them the nature of the change. Views can then inquire of the model about its new state, and update their display if necessary. Controllers may change their method of interaction depending on the new state of the model. This message-sending is shown diagrammatically in Figure 1.

An Implementation of Model-View-Controller

The Smalltalk-80 implementation of the Model-View-Controller metaphor consists of three abstract superclasses named *Model*, *View*, and *Controller*, plus numerous concrete subclasses. The abstract classes hold the generic behavior and state of the three parts of MVC. The concrete classes hold the specific state and behavior of the application facilities and user interface components used in the Smalltalk-80 system. Since our primary set of user interface components were those needed for the system's software development tools, the most basic concrete subclasses of *Model*, *View*, and *Controller* are those that deal with scheduled views, text, lists of text, menus, and graphical forms and icons.

Class Model

The behavior required of models is the ability to have dependents and the ability to broadcast change messages to their

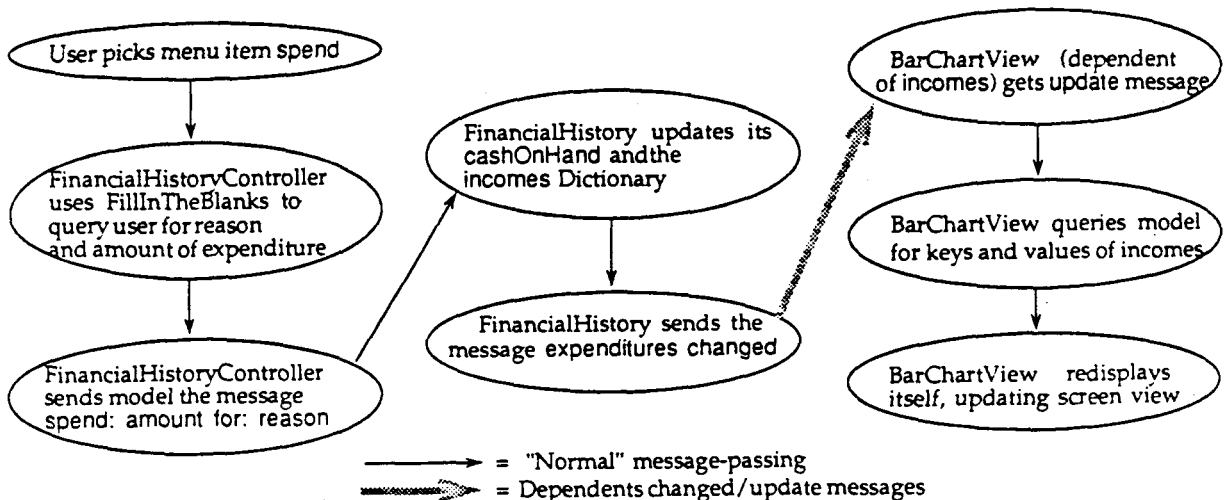

Figure 2. FinancialHistoryView with its BarChart subviews, the Controller's menu, and an interaction prompter (note that the menu and prompter are never visible at the same time)

dependents. Models hold onto a collection of their dependent objects. The class *Model* has message protocol to add and remove dependents from this collection. In addition, class *Model* contains the ability to broadcast change messages to dependents. Sending the message `changed` to a *Model* causes the message `update` to be sent to each of its dependents. Sending the message `changed: aParameter` will cause the corresponding message `update: aParameter` to be sent to each dependent.

A simple yet sophisticated MVC example is the FinancialHistoryview tutorial found in [Goldberg and Robson 83]. A display of a FinancialHistory is shown in Figure 2 and its implementation is discussed in the MVC implementation examples at the end of this article. In it, a view that displays a

Figure 3. Message-sending and dependency updating for an example from the FinancialHistory application

bar chart is created as a dependent of a dictionary of tagged numerical values (for example, **rent** ≥ \$500). The composite **FinancialHistoryView** has two subviews, with two bar charts, whose models are two distinct dictionaries (incomes and expenditures). These are held as instance variables of the central model, an instance of class **FinancialHistory**.

Figure 2 also shows the pop-up menu used by the **FinancialHistoryController** with the two items labeled 'spend' and 'receive' as well as the input prompter (a **FillInTheBlank**) querying for an amount of be spent on 'good times'.

User action for interacting with the **FinancialHistory** application might be to pick an item from a menu to add a new amount for rent. The controller then sends a message to the model (the dictionary), and the model sends **self changed**. As a result of this, the bar chart is sent the message **update**. In response to that message, the bar chart gets the new values from the dictionary and displays the new bars using the display messages. A flow diagram for this MVC interaction might look like Figure 3.

The change messages with parameters (i.e., **self changed:someAspect**) are used to pass information from the model to its dependents about which aspect has changed, so as to minimize the amount of view updating needed. For example, the object **householdFinances** (the model mentioned earlier that holds onto the dictionaries of income and expenses), could have been the model of two bar chart views, with separate protocols for displaying expenses and income. In this case, the update message could contain a parameter saying which of the aspects (expenses or income) had changed.

Depending on the application, many of the basic Smalltalk-80 system structure classes can serve as models of MVC systems. Views can be found in the system or user applications that use very simple objects (numbers or strings), collection class instances (**orderedCollections**, dictionaries, bitmaps or display texts) or complex composite objects (networks, databases, event lists, or financial histories) as their underlying models.

Class View

The abstract superclass, class **View**, contains the generic behavior of views in the system. This includes model and controller interaction, subview and superview interaction, coordinate transformation, and display rectangle actions. The many subclasses of **View** implement the various display interaction tools used in the user interface.

Every instance of a view has exactly one model and exactly one controller. The model is normally set explicitly. Because view and controller classes are often designed in consort, a view's controller is often simply initialized to an instance of the corresponding controller class. To support this, the message **defaultControllerClass**, that returns the class of the appropriate controller, is defined in many of the subclasses of view.

Views have the ability to have zero or more subviews, with flexible coordinate transformations between one view and its super- and subviews. Instances of class **View** have instance variables for their supervIEWS and for a (possibly empty) collection of subviews, as well as for an instance of class

WindowingTransformation which represents the transformation (translation and scaling) between that view's coordinate system and that of its superview. In addition, there is a default protocol in **View** for adding and removing subviews, as well as a protocol for changing the transformations. This allows views consisting of many subviews to be pieced together flexibly and simply.

The third type of behavior in class **View** is that which relates to displaying. Because subclasses of **View** are assumed to use display objects to actually do their displaying (**Forms**, **Pens**, **Lines**, or instances of other graphical classes), **View** only supports generic displaying behavior. In particular, there is no instance variable for display objects. Class **View** assumes that the top level of a subview structure displays on some medium (typically the display screen).

Views therefore cache the transformation from their own internal coordinate system to the display's coordinate system (i.e., the composition of the view's transformation and all of its supervIEWS' transformations), so that it is faster to get from a view's internal space to display space. **View** also has instance variables **insetDisplayBox**, the clipping rectangle within which the view may display without overlapping other views; **borderWidth** and **borderColor**, to define the (nonscaled) borders between a view and its superview; **insideColor**, to define the color (if any) with which a view colors its **insetDisplayBox** before actually displaying its contents; and **boundingBox**, to describe the extent of display objects within the view's coordinate system.

By default, the message **model: anObject**, when sent to a view, initializes the view's controller to be a new instance of the view's default controller class. It establishes **anObject** as the model for both the view and the controller, and establishes the view as a dependent of the model. This one message is typically sufficient for setting up the MVC structure.

The message **release**, used when closing a hierarchy of views (i.e., the subviews of one top-level window), gives the programmer the opportunity to insert any finalization activity. By default, **release** breaks the pointer links between the view and controller. The message **release** also removes the view from its model's dependents collection, breaking reference circularities between them.

Class Controller

It is a controller's job to handle the control or manipulation (editing) functions of a model and a particular view. In particular, controllers coordinate the models and views with the input devices and handle scheduling tasks. The abstract superclass **Controller** contains three instance variables: **model**, **view**, and **sensor**; the last of which is usually an instance of class **InputSensor** representing the behavior of the input devices.

Because the interpretation of input device behavior is very dependent on the particular application, class **Controller** implements almost none of this behavior. The one such behavior that is implemented is the determination of whether or not the controller's view contains the cursor.

Class **Controller** does include default scheduling behavior. It takes the point of view that only one controller is to be active at a time; that is, only one controller at a time mediates user

input actions. Other views could be displaying information in parallel, but the user's actions are to be interpreted by a single controller. Thus, there is behavior in class Controller for determining whether a controller needs to receive or maintain control. In addition, there is behavior to signal initiation and termination of control, since many controllers will need to have special initiation and termination behavior.

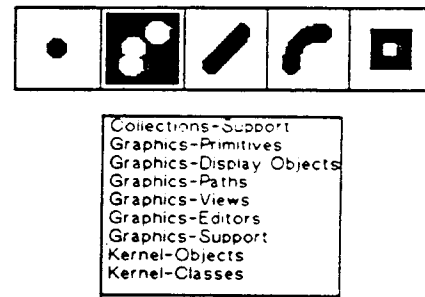

The query messages **isControlWanted** and **isControlActive** are overridden in concrete subclasses of Controller if they require a different behavior for determining whether to receive or maintain control. By default, these messages use the messages **controlToNextLevel** (pass it on down) and **viewHasCursor** (a query) in such a way that the controller of the lowest subview in the hierarchy that contains the cursor in its display box will take and retain control.

Once a controller obtains control, the default behavior is to send it the messages **controlInitialize**, **controlLoop**, and **controlTerminate**. This message sequence is found in the method **startUp**. The messages **controlInitialize** and **controlTerminate** are overridden in subclasses that want specific behavior for starting and ending their control sequences (for example, many of the list controllers have a scroll bar appear to their left only when they have control). **ControlLoop** is implemented as a loop that sends the message **controlActivity** as long as the controller retains control. This message is overridden in many controller classes to do the "real" work of the user interface.

StandardSystemView and StandardSystemController

Subclasses of View and Controller are the various classes that implement more specific types of view and controller behavior. Classes *StandardSystemView* and *StandardSystemController* are the implementation of "window System" behavior. *StandardSystemController* contains the definition of the standard *blue-button menu* (normally assigned to the right-hand mouse button), used for accessing operations of closing, collapsing, and resizing the top-level view on the display. It also contains the behavior for scheduling the view as one of the active views. *StandardSystemView* contains the behavior for top-level view labels, for displaying when collapsed or not (possibly using icons), and

Figure 5. SwitchView and ListView examples

for the size (minimum, maximum, changing) of the view on the display. Interactive applications typically exist inside system views, that is, the views and controllers for the application are created as subviews of a *StandardSystemView* (the application's top-level view).

In addition to *StandardSystemController*, the system provides other abstract controller classes with default behavior. Instances of *NoController* will never take control; they are often used in conjunction with "read-only" views. Class *MouseMenuController* includes behavior for producing pop-up menus when any of the mouse buttons is pressed. Most controllers in the user interface are subclasses of *MouseMenuController*, including *StandardSystemController* itself, because of the extensive use of pop-up menus. Another example of these abstract classes is class *ScrollController*, which implements scroll bars.

Because views are often composed of parts (composite views), with one application view containing multiple subviews (as the *FinancialHistoryView* shown in Figure 2 has subviews for the two bar chart views), the instance variables for views have different meanings in an application's *StandardSystemView* than in their subviews. Of the many subclasses of View, some are meant to behave as top-level views (such as *StandardSystemView*), and others are meant to be used as subviews (single subviews within a structured view) and "plugged in" to other views as components (such as the *SelectionInListView* used in many types of applications).

Figure 4 is a schematic diagram of the state and interrelationships of the relevant MVC objects used in the Counter-

Figure 4. Instance variables of an MVC Triad for running CounterView

The complete source code for this example is included below in the section called "MVC Implementation Examples." The interdependencies are shown by the arrows linking the model, view and controller together via instance variables and dependents.

User Interface Component Hierarchy

The classes View and Controller, along with the other abstract classes, provide the framework for views and controllers in the Smalltalk-80 implementation of the Model-View-Controller metaphor. The system also contains various subclasses of View and Controller that provide the pieces of user interface functionality required by interactive applications. These user interface components include menus, text, and forms. These components are pieced together to form the standard system views of the Smalltalk-80 application development environment, and can be reused or subclassed for system applications. They form the kernel of the component library of model-building tools and user interaction components that can be easily "pulled off the shelf" and "plugged" together to create interactive applications. We list some of them here, but in most cases we only use the names of the subclasses of View; it is assumed that each is used with one or more appropriate Controller subclasses.

SwitchView and ListView are two subclasses of View that provide static or dynamic menu behavior. SwitchViews are used, for example, in the instance/class switch of the system browser or the iconic menu of the form editor. They behave as a switch; they can either be on or off, and when the user clicks the mouse button on them, they will notify their model. These are typically used as menus of text or forms, or "buttons."

A ListView is a scrolling menu of text items, such as those used in the upper four subviews of the system browser (shown in Figure 11). It will inform its model when the user has made a new selection in the list. Figure 5 shows examples of the use of subclasses of SwitchViews (in the iconic menu of the Form-Editor, the paint program) and ListViews (in the Browser's category list subview).

Prompters and Confirmers are simple views that can be used for eliciting user input. They are started up by giving them a string for their query or prompt, and can return either a string value (in the case of Prompters) or a Boolean value (in the case of Confirmers).

Because they can be considered as belonging more to the

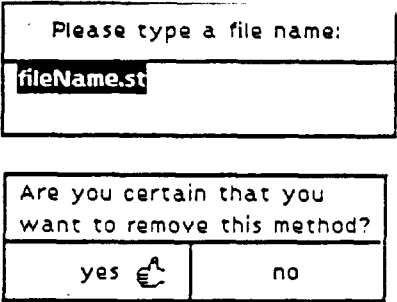

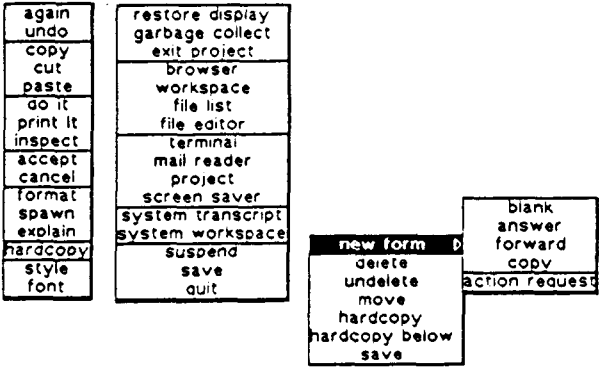

Figure 7. Examples of simple and hierarchical menus

controller-sensor interface, pop-up menus are implemented as a special kind of MVC class. Class *PopupMenu* is a subclass of **Object** and provides its own scheduling and displaying behavior. They are typically invoked by a *MouseMenuController* when the user pushes a mouse button. When invoked, *PopUpMenus* by default return a numerical value that the invoking controller uses to determine the action to perform. There are several subclasses of *PopupMenu*, some that implement hierarchical (multi-level) menus and others that return symbols instead of numerical values upon item selection. Examples of typical menus are shown in Figure 7.

A number of view/controller subclasses provide text handling components. Class *StringHolderView* and class *TextView*

Figure 8. File-based TextView and Menus

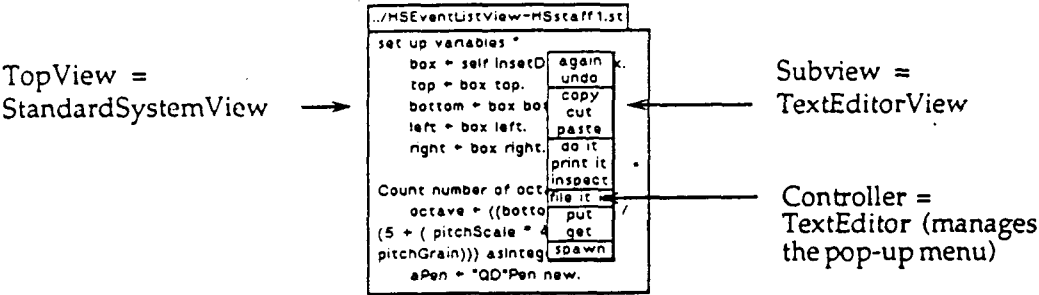

Figure 9. Simple Workspace View and Menu

provide views of text used in Workspaces, Editors, Transcripts, and other instances where text is displayed. The Controller subclasses *ParagraphEditor* and *TextEditor* have the standard text-editing functionality and are used in many text editor subviews. The layout of a file-based text editor view is shown in Figure 8 along with the names of its components.

In addition to these view types, there are several other classes provided within the system that are used in building MVC user interfaces. These include the special controller classes

mentioned earlier: *MouseMenuController* and *NoController*; and the class *InputSensor* that is used for monitoring user input. There is a global object called *Sensor* that is the sole instance of the class *InputSensor*. It is used to model the user's input devices such as the mouse and the keyboard. One can send query messages to *Sensor* such as *anyButtonPressed*, or one can wait for a user action with messages such as *waitBlue-Button*. One need normally never refer to *Sensor*, since it is used in the implementation of the more basic controller classes, but many types of special user interface components, especially those that track the mouse directly (for rubber-band lines, for example), use it.

Program Development Support Examples

Workspaces, inspectors, browsers, debuggers, and various editors are among the system views provided in the Smalltalk-80 software development support environment. They serve now as examples of piecing together subviews from the view and controller components collection with appropriate models to

Figure 10. Inspector Examples—Simple, Array and Dictionary Inspectors

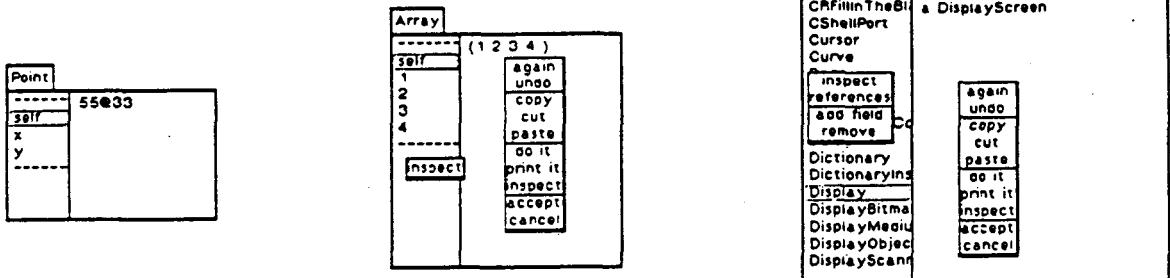

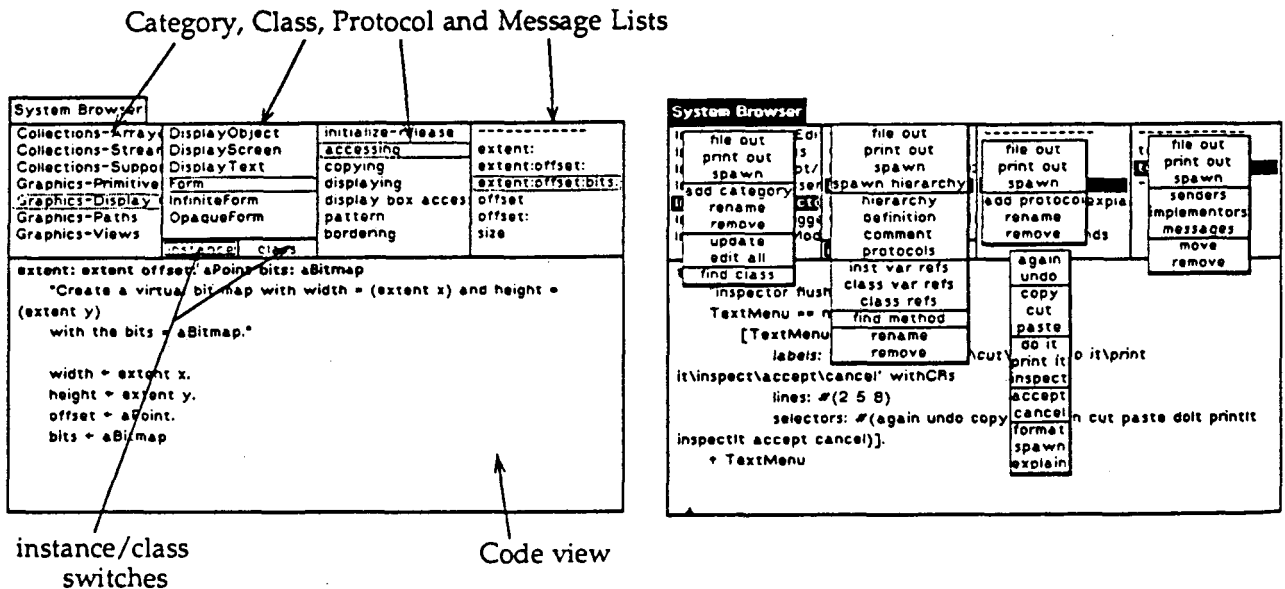

Figure 11. System Browser view layout and browser menus

the current text to display, which is the new class template. In this way, the six view/controller pairs sharing the single model work to produce the desired effect.

There are several other types of Browser found in the Smalltalk-80 system. Note the middle group of menu items in the upper-right subview (The MessageList) of the System Browser shown above. The menu items **senders**, **implementors**, and **messages** can be used to open new browsers (called *MessageSet Browsers*) on a small subset of the system messages—namely all the senders of the currently selected message, all other implementors of the same message, or all messages sent from within the method of the currently selected message. Other Browsers exist, for example, to assist in change management (*ChangeSet Browsers*) or system recovery (*ChangeList Browsers*).

Debuggers

Class *Debugger* is defined as a subclass of class *Browser*, so that it can inherit the cross-referencing behavior (menu messages for querying senders, implementors, and messages used in a method). It also inherits and augments the code view behavior. The upper subview, which is a context list (i.e., a message-sending stack), is a list view that uses protocol defined in class *Debugger* for displaying the system's message sending context stack as a list view.

Unlike the system browser, the Debugger is not the only model involved in the debugging application. There is a separate Inspector model for each of the two inspector subviews that comprise the four lower subviews. The Debugger instance holds onto those two Inspector objects as two of its instance variables; it explicitly changes the objects they are inspecting whenever a new context is selected. This is an example of using cooperating model objects with independent coordinated views. It also shows an advantage to having the Inspector class as a filter on the object: the object used as the "model" of the Inspector object can change, while the views and controllers refer to a consistent model.

Object Editors in Smalltalk-80 Applications

Along with the user interaction paradigms of browsing and inspecting, editing is one of the most important aspects of applica-

tions and software development tools. Among the standard editors available in Smalltalk-80 systems are text and file editors, form and bitmap editors for graphics, and file system editors for source code and resource management. Many Smalltalk-80-based applications implement new graphical editors for the structured objects that are specific to their application domains, such as charts, graphs, maps, networks, spreadsheets, animations, event lists, or database contents.

View/Controller Factoring and Pluggable Views

Originally, the program environment tools were implemented so as to have the models know nothing about their views and controllers and to use subclassing as the style for differentiating behavior. In this style, for example, all the knowledge for creating the appropriate pop-up menus is in the class, and there is a different class for each type of view. Each of these classes has class variables to hold the menu and the corresponding messages, and those class variables are bound to instance variables at instance creation time. Associated with each of these different controller classes was a new view class. This is still how some of the system views are implemented, and it has a number of advantages, such as clean factoring of system components.

We noticed, however, that many of these different controller and view classes shared a large number of properties, especially those that implemented list views. One similarity was that the models were almost always some sort of filter class that already knew about the lists and the selected item in the list.

The view classes tended to be identical except for the one message, **defaultControllerClass**, which is used to create the different controllers. The controllers were quite similar except for the particular set of menu items and the messages they sent themselves when an item was selected. Finally, the controller messages were almost always passed directly on to the model; that is, the method for message **aMessage**, which was sent to the controller when the menu item **aMessage** was selected, was almost always implemented as `↑model aMessage`.

It would be easier for the application developer if these differences (e.g., the message sent to the model to generate the list) were not implemented by different view/controller classes, but were made parameters (instance variables) of a single class. This is the notion called *pluggable views*. Rather than building a new kind of view (e.g., a new kind of list view) by creating two new classes, the developer creates an instance of an exist-

Figure 13. Setup message for the class list view in the browser using a pluggable SelectionInListView

classListView ← SelectionInListView	"an instance of SelectionInListView"
on: aBrowser	"model of the SelectionInListView"
aspect: #className	"message to get the selected item"
change: #className:	"message sent on item selection"
list: #classList	"message sent to generate list"
menu: #classMenu	"message sent to get menu"
initialSelection: #className.	"message sent to get initial selection"
 self addSubView: classListView	 "Add a subview to the TopView"
in: myAreaRectangle	"relative area filled by SubView"
borderWidth: 1	"border to adjacent SubViews"

item selection definitions.

In some sense, this is an engineering trade-off, because it has less flexibility than entirely new class definitions and can lead to having controller information in the models. It does, however, reduce the number of different things the developer needs to do to get an application together, as well as the number of different classes needed.

An example of the use of pluggable views is the implementation of the system browser list subviews. The original implementation had a special subclass of ListController for each of the list subviews. Each of these classes had its own definition of the menus and messages to send when the menu item was selected, and its own message to send when a new list item was selected. The current pluggable implementation has four instances of the same class, SelectionInListController, with parameters that represent the messages to be sent to the model when the selection changes, and to create an appropriate menu when the proper mouse button is pressed. The Browser model knows about the four local menus and receives the corresponding messages.

The use of the setup message for adding a pluggable SelectionInListView to a composite view is demonstrated in the Figure 13. This code segment comes from the actual view initialization for the BrowserView. It defines a SelectionInListView in the subview area described by the rectangle **myArea-Rectangle**. It uses the messages and the menu referred to in the figure.

The pluggability of SelectionInListViews is afforded by the class message shown here, namely **on:aspect:change:list:menu:initialSelection:**. The message **addSubView:in:border-Width:** is defined in class View for the composition of complex view/subview layouts. Messages of this type are the essence of subview pluggability and examples of their use and utility are available through out the system's user interface classes. Several other classes of pluggable subviews implement similar instantiation (*plugging*) messages.

Another example of a pluggable view is the text view used in many system views. In this case, one wants to plug a text editor subview into a view and tell it the messages needed for it to access its new text contents, to set its model's text, and to display its menu. The message that is implemented in the class CodeView for this is **on:aspect:change:menu:initialSelection:** (note the similarity between this and the message used above for a pluggable SelectionInListView). The example message in Figure 14 is the entire method used to define a FileEditor view such as the one shown in Figure 8.

Several of the other views can be used with pluggable instantiation messages. These include the switch views (which one passes a label, the messages they send to determine their state and respond to being pressed), and confirmers and prompters (one passes them a message or prompt and they return strings or Boolean values).

Models and MVC Usage

Class Object contains behavior that supports Model's functionality, i.e., the ability for any object to have dependents, and

able of class Object called *DependentFields*, whose keys are models and whose corresponding values are collections of those models' dependents. Class Object also implements the message protocol to deal with adding and removing dependents. For example, when some object (like **aModel**) receives the message **add-Dependent: someView**, then **someView** is added to the collection found in the *DependentFields* dictionary at key **aModel**.

Since views and controllers hold direct pointers to their models, the *DependentFields* dictionary creates a type of circularity that most storage managers cannot reclaim. One by-product of the release mechanism is to remove an object's dependents which will break these circularities, so this is typically not a problem except when developing an MVC application. The corresponding circularities that result from using instances of Model are the direct kind that most storage managers can reclaim. Therefore, we encourage the use and subclassing of Model.

There are several more sophisticated aspects of advanced MVC application that are not covered in this article. These include the use of windows and viewports, flexible scrolling frameworks, text composition and fonts, and view composition with nonscaling subviews. These issues can be studied via their usage within the Smalltalk-80 system or through examples found in Smalltalk-80 system applications. Interested readers are also referred to back issues of the *ParcPlace Newsletter* (formerly the *Smalltalk-80 Newsletter*) from ParcPlace Systems and the *OOPSTAD HOOPLA Newsletter* (see addresses in the reference list).

MVC Implementation Examples

Presented next are three MVC implementation examples: one a full application for a very simple view type (a Counter view); one a new application view using pluggable components (the Organizer view); and one a condensed listing for the viewing components of a more complex application (the Financial-History view discussed earlier and shown in Figure 2).

CounterView Example

The Counter demonstration and tutorial example is part of the standard Smalltalk-80 Version VI 2.2 release package and was originally written by Michael Hanus of the University of Dortmund. It implements a model (an instance of class *Counter*) that is a simple numerical value and view (a *CounterView*) on it which shows the value of the Counter. The controller (*CounterController*) implements a menu allowing one to increment or decrement the Counter's value. The complete code for these three classes follows.

First one must define a class named *Counter* as a subclass of Model in the system class category named *Demo-Counter*. Counter has one instance variable for its value.

```
Model subclass: #Counter
instanceVariableNames: 'value'
classVariableNames: ''
```

Figure 14. Open Message for a FileEditorView using a Pluggable CodeView.

```
FileModel class methodsFor: 'instance creation'
open: aFileModel named: aString
    "Scheduled a view whose model is aFileModel and whose label is aString."
| topView codeView |
    "local variable for my top-level view and 1 subview"
    "set up the top-level standard system view"
topView ← StandardSystemView model: aFileModel
    label: aString
    minimumSize: 180@180.
codeView ← CodeView
    on: aFileModel
    aspect: #text
    change: #acceptText:from:
    menu: #textMenu
    initialSelection: nil.
topView addSubView: codeView
    in: (0@0 extent: 1@1)
    borderWidth: 1.

topView controller open
```

```
"pluggable CodeView setup message"
"it takes its model and the following:"
"message sent to the model to get the text"
"message sent to accept a new text"
"message sent to get text view's menu"
"initially-selected text"
"add the code view as the sole subview"
"use the entire view's area"
"with a 1-pixel border"
```

```
"open the default controller to start up view"
```

```
poolDictionaries: ''
category: 'Demo-Counter'
```

```
"Answer an initialized instance of the receiver."
↑super new initialize
```

Next, one adds methods to Counter for initializing new counter instances and for accessing their values. These messages will then be understood by all Counter instances.

Now define a class for the controller, along with the methods to define the menu it uses and those that implement the menu functions by passing them along to the model. The controller inherits all its instance variables from its superclasses.

```
Counter methodsFor: 'initialize-release'
initialize
```

```
MouseMenuController subclass: #CounterController
instanceVariableNames: ''
classVariableNames: ''
poolDictionaries: ''
category: 'Demo-Counter'
```

```
"Set the initial value to 0."
self value: 0
```

```
Counter methodsFor: 'accessing'
value
```

```
CounterController methodsFor: 'initialize-release'
initialize
```

```
"Answer the current value of the receiver."
↑value
```

```
"Initialize a menu of commands for changing the
value of the model."
super initialize.
```

```
value: aNumber
    "Initialize the counter to value aNumber."
    value ← aNumber.
    self changed:"to update displayed value"
```

```
self yellowButtonMenu: (PopUpMenu labels:
    'Increment\Decrement' withCRs)
yellowButtonMessages: #(increment decrement)
```

```
Counter methodsFor: 'operations'
decrement
```

```
CounterController methodsFor: 'menu messages'
decrement
```

```
"Subtract 1 from the value of the counter."
self value: value - 1
```

```
"Subtract 1 from the value of the counter."
self model decrement
```

```
increment
```

```
increment
```

```
"Add 1 to the value of the counter."
self value: value + 1
```

```
"Add 1 to the value of the counter."
self model increment
```

Add the method to class Counter to be used for getting a new counter instance.

```
CounterController methodsFor: 'control defaults'
isControlActive
```

```
Counter class methodsFor: 'instance creation'
new
```

```
"Take control when the blue button is not pressed."
```

```
↑super isControlActive &  
sensor blueButtonPressed not
```

Next, define the class CounterView as a subclass of View with no additional instance variables.

```
View subclass #CounterView  
instanceVariableNames: ''  
classVariableNames: ''  
poolDictionaries: ''  
category: 'Demo-Counter'
```

Add to it methods for displaying the state of its model (a Counter) in the view shown in Listing 1.

Define a method for updating the view when the model changes. The model's sending a **self changed** message will cause the view to be sent an update message.

```
CounterView methodsFor: 'updating'  
update: aParameter  
    "simply redisplay everything."  
    self display
```

Another method is needed to return the class of the default controller used within a counterView.

```
CounterView methodsFor: 'controller access'  
defaultControllerClass  
    "Answer the class of a typically useful controller."  
    ↑CounterController  
CounterController initialize-release'
```

Finally, a method is needed to open up a new counterView and set up the model and controller for it. The resulting view and its menu are shown in Figure 15.

Discussion

The code presented so far is the most trivial sort of complete MVC implementation. Suppose now that we wish to add push-buttons to the view instead of having menu items to increment and decrement the value of the counter. Using pluggable button

Listing 1.

```
CounterView MethodsFor: 'displaying'  
displayView  
    "Display the value of the model in the receiver's view."  
    | box pos displayText |  
    box ← self insetDisplayBox.           "get the view's rectangular area for displaying"  
  
    pos ← box origin + (4 @ (box extent y / 3)). "Position the text at the left side of the area, 1/3 of the way down"  
  
    displayText ← ('value:', self model value printString) asDisplayText. "concatenate the components of the output string and display them"  
  
    displayText displayAt: pos
```

views, this can easily be done by writing a new open method for the CounterView, as shown in Listing 2.

In the open method, one sees the setup of the view as a composition of its three subviews. The subview placement is done via the definition of relative rectangles. These relative rectangles are displayed in the left-hand figure in Figure 16. The definitions of the two SwitchViews and their Buttons sets their actions so that they send the **increment** and **decrement** messages to the model of the view. This will then have the desired effect of changing the value of the model (a Counter).

Hierarchical Text Organizer

The second example is the implementation of a simple browser view on a 2-level hierarchical text. It presents a view with two subviews: a list of topics and a text view for the selected topic's text. The model is an organizer, which holds onto its organization in a dictionary of text keys and text values. The keys are used in the topic list view and the values are the contents of the text view. The layout and menus of an organizer are shown in Figure 17.

The Organizer is included here as an example of a more sophisticated use of pluggable views and also as an example of MVC class factoring. In this example, the single class (Organizer) implements the functionality of the model and the view and also defined the menus used in the view's two subviews.

The organizer class has two instance variables; its organization dictionary and the currently selected category (topic, section).

```
Model subclass: #Organizer  
instanceVariableNames: 'organization'  
currentCategory'  
classVariableNames: ''  
poolDictionaries: ''  
category: 'Interface-Outlines'
```

The most basic messages to an organizer are for setting it up and for accessing the organization by category.

```
Organizer methodsFor: 'initialize-release'  
initialize
```

```

The methods used to parse streams assume that special strings are used for separating entries from their keys and for separat-

many common file formats (such as System Workspaces, password files, or tables) to be parsed with organizers.

Organizer methodsFor: 'parsing'

parseFrom: aStream entrySeparatorString: entryStr
keySeparatorString: aKeyStr

```
"read an organization from the given stream using
the two given strings to
parse the contents into entries and values"
```

```
|tmp key body|
```

```
[aStream atEnd] whileFalse:
```

```
[tmp ← ReadStream on: (aStream upToAll: entry-
Str).
```

```
key ← tmp upToAll: aKeyStr.
```

```
body ← tmp upToEnd asText.
```

```
organization at: key put: body]
```

The class messages for organizers provide for the creation of new instances and the simple loading of standard files.

The organizer described above can be used, for example, for creating a browser on the contents of the Smalltalk-80 system's System Workspace, as shown in Figure 17.

FinancialHistory Example View Setup

On the following pages is a condensed version of the source code (Listings 4 and 5) for the classes *FinancialHistory*, *FinancialHistoryView*, and *FinancialHistoryController* as described in depth in [Goldberg and Robson 83] and the ParcPlace Systems Smalltalk-80 VI 2.3 release fileset. Figure 2 shows the view layout and standard menu for the FinancialHistory example. Included here is the method text for the MVC-related setup and interaction messages.

The controller class implements the default menus for use within *FinancialHistoryView* as shown below. It carries out user queries and sends messages to the model to change the state (such as after spending or receiving money).

Only the **receive** message for the controller is shown above; the **spend** message is closely analogous to it.

The class *FinancialHistoryView* simply contains the view setup message for plugging the two *BarChartViews* into a top-View and starting the appropriate controller.

classes for the FinancialHistory example and are the bar chart elements seen in Figure 2.

The three examples presented here show some of the sophistication possible using the Model-View-Controller paradigm and methodology in the Smalltalk-80 system. Readers are encouraged to browse the Smalltalk-80 system interface classes or read the other references to see many more examples of MVC programming.

Summary

The Model-View-Controller metaphor is a way to design and implement interactive application software that takes advantage of modularity, both to help the conceptual development of the applications, and to allow pieces already developed for one application to be reused in a new application.

The metaphor imposes a separation of behavior between the

actual model of the application domain, the views used for displaying the state of the model, and the editing or control of the model and views.

We have implemented the metaphor in the Smalltalk-80 system and have used this implementation both to create the basic programming development tools used in the system, and to develop a diverse collection of applications.

Acknowledgements

The Smalltalk-80 Programming System and the MVC user interface paradigm were developed over several years by numerous members of the Systems Concepts Laboratory at the Xerox Palo Alto Research Center (PARC).

Several of our colleagues at Xerox PARC and ParcPlace Systems reviewed and contributed to this paper. We are indebted to them for their assistance.

To find out more about the use of the MVC classes within the Smalltalk-80 system, interested readers are referred to the system itself. Using the MessageSet browsers for browsing all senders of the pluggable view initialization messages can be very informative. Examples of these might be found in the "plugging" message **on:aspect:change:menu:initialselection:** which is implemented in class CodeView or the parallel messages in the other pluggable view classes such as SelectionInListView or SwitchView.

One can also browse all references to the simple interactive user interface classes (such as FillInTheBlank or BinaryChoice), or the **open** messages for the system's application views. For examples of advanced interaction usage, looking at implementors of the message **controlActivity** can be instructional.
